We forecast the prospective of detection for a stochastic gravitational wave background sourced by cosmological first-order phase transitions. We focus on first-order phase transitions with negligible plasma effects, and consider the experimental infrastructures built by the end of the LISA mission. We make manifest the synergy among LISA, pulsar time array experiments, and ground-based interferometers. For phase transitions above the TeV scale or below the electroweak scale, LISA can detect the corresponding gravitational wave signal together with Einstein Telescope, SKA or even aLIGO-aVirgo-KAGRA. For phase transitions at the electroweak scale, instead, LISA can be the only experiment observing the gravitational wave signal. In case of detection, by using a parameter reconstruction method that we anticipate in this work, we show that LISA on its own has the potential to determine when the phase transition occurs and, consequently, the energy scale above which the standard model of particle physics needs to be modified. The result may likely guide the collider community in the post-LHC era.

GRAvitational-waves Science&technology Symposium - GRASS2018

1-2 March 2018

Palazzo Moroni, Padova (Italy)

*Speaker.

1. Introduction

Several phenomena in the early universe generate a Stochastic Gravitational Wave Background (SGWB) that can be detected by current or forthcoming Gravitational Wave (GW) experiments [1, 2, 3]. The observation of a GW signal associated to any of these sources would be a milestone in the understanding of nature. It would be the first *direct* measurement of the properties of the universe before the cosmic microwave background fingerprint, and would put on firm observational ground an epoch prior to Big Bang Nucleosynthesis (BBN).

The SGWB associated to a cosmological First-Order Phase Transition (FOPT) is certainly one of the most investigated. The Standard Model of particle physics (SM) predicts that no cosmological FOPT has ever occurred [4]. Nevertheless, many theoretical and empirical observations (e.g. the hierarchy problem, the dark matter, and the baryon-asymmetry of the universe) suggest that the SM cannot be the ultimate theory, and many completions of the SM have been proposed to solve some of its theoretical issues. Remarkably, several of them predict a cosmological FOPT SGWB in the LISA frequency band [1].

The spectrum of GW energy density per logarithmic frequency interval of a SGWB is defined as $\Omega_{\text{GW}}(f) \equiv \rho_c^{-1} d\rho_{\text{GW}}/d(\log f)$, with $d\rho_{\text{GW}}$ being the GW energy density in the interval f and $f + df$, and $\rho_c = 8 \times 10^{-47} h^2 \text{GeV}^4$ the critical density normalized by the Hubble scale factor $h \simeq 0.67$. For a cosmological FOPT, this spectrum can be expressed in terms of a few effective parameters that describe the particle content of the plasma and its interactions with the fields triggering the phase transition. For simplicity hereafter we focus on setups where such interactions are negligible and the FOPT has substantial supercooling¹. In this case the SGWB spectrum can be written as [1, 5, 6]

$$h^2 \Omega_{\text{GW}}(f) \simeq h^2 \bar{\Omega}_{\text{GW}} \frac{3.8(f/f_p)^{2.8}}{1 + 2.8(f/f_p)^{3.8}}, \quad (1.1)$$

where the (normalized) amplitude and frequency of the peak of the signal are respectively

$$h^2 \bar{\Omega}_{\text{GW}} \simeq \frac{8}{10^5} \left(\frac{H_\star}{\beta} \right)^2 \frac{\xi(v_w)}{\sqrt[3]{g_\star}}, \quad f_p \simeq \frac{7.7}{10^5} \tilde{\xi}(v_w) \left(\frac{\beta}{H_\star} \right) \frac{T_\star \sqrt[6]{g_\star(T_\star)}}{100 \text{GeV}} \text{ Hz}, \quad (1.2)$$

with

$$\xi(v_w) = \frac{0.11 v_w^3}{0.42 + v_w^2}, \quad \tilde{\xi}(v_w) = \frac{0.62}{1.8 - 0.1 + v_w^2}. \quad (1.3)$$

The frequency shape of the spectrum thus depends on various parameters: the velocity at which the bubble collide (v_w); the temperature at which the FOPT ends (T_\star); the inverse of the FOPT duration normalized by the Hubble factor at the completion of the transition (β/H_\star); and the number of relativistic species in the thermal bath after the transition ($g_\star(T_\star)$). A FOPT occurring during the electroweak symmetry breaking typically exhibits T_\star of the order of 100 GeV, while the values of β/H_\star and v_w are very model dependent. Most of the SM extensions provide $g_\star(T_\star \simeq 100 \text{ GeV}) \approx 106$. Nevertheless, there are no model-independent experimental constraint preventing FOPT at temperatures far away from the electroweak scale, so that the frequency of the peak, f_p , can span

¹The analysis we are presenting could be straightforwardly repeated for scenarios with small supercooling or plasma contributions. The only complication is the larger dimensionality of the effective-parameter spaces to study.

Figure 1: *Left panel:* The value of the frequency peak f_p in the parameter space $T_*-\beta/H_*$ for bubble velocities $v_w = 0.99$. On the background (colored bands) the frequencies the forthcoming GW detectors are sensitive to; the stronger the color, the better the sensitivity. The blue area is excluded by the BBN bound. *Right panel:* Sensitivity curves of the current and forthcoming GW experiments and the SGWB signals (dotted curves) sourced by the FOPT benchmark scenarios with $g_* = 106$, $\beta/H_* = 3$, and T_*/GeV and v_w being respectively 3 and 0.99 (dotted purple line), 3 and 0.05 (dotted gray line), 120 and 0.99 (dotted magenta line), 120 and 0.05 (dotted orange line), 10^4 and 0.99 (dotted blue line), and 10^4 and 0.05 (dotted green line). The dotted-dashed lines correspond to the power-law sensitivity curves of PPTA & EPTA & NANOGRV (at frequencies $f \sim \text{nHz}$) and aLIGO O1 (at frequencies $f \sim 100 \text{ Hz}$); the solid lines correspond to the sensitivity curves $\Omega_{\text{sens}}(f)$ of SKA observing 100 milli-second pulsars (dark red), SKA observing 2000 milli-second pulsars (light red), LISA (orange), ET (yellow), and aLIGO-aVirgo-KAGRA network at its final design (green). The BBN bound rules out the FOPT SGWB signals touching the blue area.

many orders of magnitude, as shown in Fig. 1 (left panel). Fig. 1 also shows $h^2\Omega_{\text{GW}}(f)$ for some illustrative FOPT scenarios (dotted curves in the right panel).

LISA is particularly sensitive, but not limited, to FOPT at the electroweak scale. Due to the frequency broadband of $\Omega_{\text{GW}}(f)$, LISA can detect FOPTs with $10^{-3} \text{ GeV} \lesssim T_* \lesssim 10^7 \text{ GeV}$ and β/H_* up to 10^3 when bubbles are ultrarelativistic, $v_w \simeq 1$ [1]. For the same reason, a FOPT signal detected at LISA can in principle be observed at the most diverse frequencies. On the other hand, depending on the FOPT parameter region, other experiments can have better chances to detect the signal. In view of this feature we now estimate the parameter reach of the current and forthcoming GW network (Section 2), sketch how well LISA can reconstruct the FOPT signal (Section 3) and comment on the implications that such a reconstruction has on the whole GW detector network (Section 4).

2. Synergy between different GW observatories

Pulsar time array experiments such as PPTA, EPTA and NANOGRV are currently testing the frequency band $\mathcal{O}(1)\text{--}\mathcal{O}(10^3)$ nHz, while present ground-based interferometers are probing the $\mathcal{O}(10)\text{--}\mathcal{O}(10^4)$ Hz range. The lack of detection in the collected data [7, 8, 9, 10] rules out

Figure 2: The parameter reach of the future GW experiment network for $v_w = 0.99$ (left panel) and $v_w = 0.05$ (right panel). In each area the corresponding experiment (see labels) detects the FOPT with $\text{SNR} > 10$. The BBN bound rules out the blue region. The bullet points correspond to the benchmark SGWB signals appearing with the same color in the right panel of Fig. 1.

any SGWB with a power-law power spectrum (i.e. $\Omega_{\text{GW}}(f) = \Omega_0 f^n$ with Ω_0 and n constants) that intersects the *power-law sensitivity curves* displayed in Fig. 1 (right panel, dotted-dashed curves). The lack of detection can be converted into an exclusion bound on $h^2 \Omega_{\text{GW}}(f)$ and the corresponding FOPT effective parameters. This bound rules out the etched parameter areas in Fig. 2.

In the future, the two aforementioned frequency ranges will be partially extended with SKA and Einstein Telescope (ET), and most of the intermediate frequencies will be covered by LISA. The right panel of Fig. 1 displays the (non power-law) sensitivity curves of SKA (dark red and light red), LISA [11] (orange), aLIGO in its final design [12] (green), and ET (yellow) [13]. For the two SKA curves we follow Ref. [14] and assume observation of 100 (dark red) or 2000 (light red) milli-second pulsars [15]. For the forecast of the FOPT parameter reach we consider GW data that will be presumably collected by the (nominal) end of the LISA mission, in the late 2030s². The findings are shown in Fig. 2. Different colored areas correspond to different detectors. Inside each area the associated experiment detects the FOPT SGWB with a Signal to Noise Ratio (SNR) larger than 10, with SNR given by

$$\text{SNR}_i = \sqrt{(3.16 \times 10^7 \text{s}) \frac{\mathcal{T}_i}{1 \text{ year}} \int_0^\infty df \frac{\Omega_{\text{GW}}^2(f)}{\Omega_{\text{sens},i}^2(f)}}, \quad (2.1)$$

with $\Omega_{\text{sens},i}(f)$ being the sensitivity curve of the i experiment having stored \mathcal{T}_i years of data. Due to the uncertainties on the time schedules and duty cycles of all these detectors, it seems sensible to take $\mathcal{T}_i = 3, 7, 8,$ and 20 years for $i = \text{“LISA”, “ET”, “aLIGO design”, and “SKA”}$ respectively, but of course the findings are indicative.

²The LISA mission nominally ends around six years after its launch. Nevertheless, after this period, LISA should still be able to take data.

Figure 3: Reconstruction of the FOPT SGWB signals (blue lines) displayed in the left panel of Fig. 1 by means of the “multi-bin” procedure assuming a good knowledge on the LISA instrumental noise (red curves). The power-law fit is performed inside several intervals indicated by vertical yellow dashed lines. The $1\text{-}\sigma$ uncertainties are represented by the light blue band. The signal reconstruct is performed only where the error bands are displayed.

The BBN constraint, which limits the amount of radiation during the formation of the primordial elements, imposes an upper bound on the SGWB [3] and, in turn, on $\overline{\Omega}_{\text{GW}}$ [15]. Due to this constraint, in the right panel of Fig. 1, the FOPT SGWB power spectra entering the blue region are ruled out. Equivalently, the blue parameter areas in Fig. 1 (right panel) and Fig. 2 are experimentally excluded.

The outcome of the forecast is remarkable: in around twenty years, if $\beta/H_\star \lesssim 10^4$, the full network of GW observatories will be able to test a substantial part of the FOPT effective parameter space. Moreover, in a wide fraction of this parameter space, at least two experiments will be able to detect independently the signal with $\text{SNR} > 10$.

3. Parameter reconstruction at LISA

As previously stated, several phenomena may have generated a SGWB. Therefore, given a SGWB detection, insights on the source are possible only by means of an accurate characterization of the signal. Obviously, in the case of the cosmological FOPT, the reconstruction of the frequency shape $\Omega_{\text{GW}}(f)$ would be a key information. Here we anticipate how LISA data can be analyzed to infer the frequency shape of a SGWB with high SNR [16]. For the present purposes, we apply this method to the FOPT benchmark signals with $\nu_w = 0.99$ displayed in the right panel of Fig. 1 (magenta and blue curves).

Those benchmark signals are not well described by a single power-law in the entire LISA frequency band. Ref. [17] investigates a parameter reconstruction for a SGWB whose frequency dependence is a power law. In particular, Ref. [17] shows that one can reconstruct the amplitude and slope of the signal, if its SNR is of order 10 or larger. The SNR of our benchmark signals is several orders of magnitude larger than this value. Hence, we can split the total LISA frequency band in small subintervals – the bins – each characterized by sufficient SNR, and accurately reconstruct within each bin the signal frequency shape in terms of a power-law [16]. Optimization and

iteration of this procedure leads to the reconstruction of a SGWB in the entire frequency band in terms of a series of power laws. Applying this procedure to our benchmark signals provides the reconstructions shown in Fig. 3. Notice that the intervals within which we perform the power-law reconstruction are not equally spaced. This is due to several reasons: among them, the SNR "density" (i.e. the amount of SNR within a fixed frequency spacing) is not constant due to the frequency dependence of Ω_{GW} , and we must ensure that each bin contains a fraction of signal with sufficient SNR for being correctly reconstructed.

As Fig. 3 highlights, the benchmark signals we consider can be reconstructed quite accurately. The uncertainty on the position of the peak and its amplitude is rather small. The detailed information that can be extracted by means of this multi-power-law reconstruction is matter of future investigations [18]. It is however clear that, if LISA detects a strong cosmological SGWB, we will likely be able to decipher the origin of the signal. In particular, in case we detect a strong FOPT SGWB, from the reconstruction of the position and amplitude of the peak we can likely understand the energy scale at which the FOPT occurred, an outstanding information that can guide the particle physics community searching for the particle completion of the SM.

4. Conclusions

Several models of particle physics predict a cosmological FOPT. We investigated the future prospect for the detection of the SGWB that such transitions produce. The results we obtained apply to scenarios where the plasma plays a minor role in the production of the total SGWB: on the other hand, our qualitative conclusions depend only marginally on this assumption.

We considered the current PPTA, EPTA, NANOGRAV and aLIGO bounds on the SGWB, and shown that they poorly constrain the FOPT parameter space. On the contrary, the parameter reach of the future GW network of SKA, LISA, ET and aLIGO-aVirgo-KAGRA is definitively more promising: by the end of the LISA mission, this network will probe a large fraction of the FOPT parameter space. If bubbles expand ultrarelativistically, any cosmological FOPT with $\beta/H_* \lesssim 10^2$ and $10^{-3} \text{ GeV} \lesssim T_* \lesssim 10^8 \text{ GeV}$ will be detected with $\text{SNR} > 10$. The parameter space that can be probed remains considerable, although somehow reduced, for subsonic bubbles. In particular, due to the broadband of the FOPT SGWB, more than one detector is often sensitive to the same signal. There is then a manifest synergy between future GW experiments that will allow to probe the shape of a SGWB signal at different frequencies, in case of a detection. The SGWB frequency shape carries valuable information about the processes that produced the signal³. To highlight this issue, we have considered some illustrative FOPT SGWBs with peaks inside the LISA band. By means of a "multi-bin" reconstruction procedure, we have shown that LISA has the potential to accurately reconstruct the signal. Recovering the position and amplitude of the signal peak has rich implications. For instance (assuming a robust theoretical modellization of the FOPT signal) it allows to infer from the LISA data the FOPT contribution to the SGWB measured in other detectors (e.g. SKA or ET) – conclusion that those experiments could not reach independently if the signal is dominated by other SGWB sources. The position and amplitude of the peak, moreover, allow one to estimate at which energy scale new physics beyond the SM should emerge. This will be a key information for the collider community if no deviations from the SM will be found at the LHC.

³Correlations between cosmological sources and signal shapes have been also studied in Refs. [19, 20].
